Intestinal malrotation in the older child: A call for vigilance

Oluwafunmilayo Funke Adeniyi, Elizabeth O. Ajayi, Olumide A. Elebute¹, Mary A. Lawal

INTRODUCTION

Malrotation of the gut refers to abnormal positioning of the intestine within the peritoneal cavity and this may involve the small intestine or the large intestine.[1] Midgut malrotation usually results when the counterclockwise rotation of the gut does not take place and the duodenojejunal (DJ) junction is displaced to the right of the midline.[1,2] This is usually accompanied with nonrotation and incomplete rotation of the superior mesenteric artery. The incidence of the condition is said to be about 1 in 6000 births[3] and 85% of cases present in the first 2 weeks of life. However, in minority of cases, the patient becomes symptomatic only in adolescence or adulthood. Some individuals actually remain asymptomatic and are never diagnosed throughout their lifetime.[2]

At present, the incidence in African children is unknown and there are few reports documenting the occurrence of this condition in older African children; thus, the aim of this study is to remind physicians to include intestinal malrotation in the differential diagnosis of children who present with recurrent abdominal pain, especially when it is associated with bilious vomiting and other gastrointestinal (GI) symptoms.

SUBJECTS AND METHODS

The clinical records of children above the age of 1 year who presented with recurrent abdominal pain with or without vomiting between January 2013 and October 2015 at the Lagos University Teaching Hospital were reviewed. Information obtained from the records included clinical features, namely, abdominal pain, vomiting, abdominal distension, nausea, constipation, and passage of bloody stools. Radiological investigations, namely, abdominal X-rays, upper GI series, abdominal computerized tomography (Abd CT) scan, and other investigations done were also documented. Intraoperative findings and the outcome in each patient were also recorded.

RESULTS

Twenty-three children above the age of 1 year were seen with abdominal pain during the study period. Five (21.7%) of these children had malrotation of the gut [Table 1].

The median age of the children with malrotation was 7.0 years (range: 15 months–10 years). Eighty percent of the subjects with the condition were aged 5 years and above. The most common presenting symptoms were intermittent colicky abdominal pain in 5 (100%) and recurrent vomiting in 5 (100%) of the subjects. Vomiting was bilious in 4 (80%) of the cases. These symptoms dated back to infancy in 80% of the subjects. Other clinical features included failure to thrive, weight loss, and fever in 2 (40.0%) of the patients, respectively. One of the patients, a 15-month-old male child had genotype SS; another subject, a 10-year-old male had genotype AC.

Regarding investigative procedures, only one patient had positive findings on abdominal X-ray which showed a distended stomach. Abdominal ultrasound (Abd USS) showed gastric outlet obstruction and a dilated stomach and proximal duodenum in two of the subjects. Abd USS was reported normal in the remaining subjects. Two subjects had upper GI series (10-year-old male and 15-month-old sickle cell disease subject). The GI series in the latter revealed the DJ junction to the right of the midline. Only one of the subjects had upper GI endoscopy done and this was reported as normal.

Preoperative diagnosis was possible in 3 (50%) patients, with the use of Abd CT scan and this revealed situs inversus [Figure 1] (right-sided stomach and left-sided liver and gall bladder) and midgut volvulus in the one of the patients.

A Ladd’s procedure was performed in all patients in this series. Operative findings included obstructing bands of Ladd (100%) and volvulus (16.7%) with situs inversus (16.7%) [Figures 2 and 3]. Symptoms were relieved satisfactorily and quickly with surgical intervention.

DISCUSSION

In this series, five children above the age of 1 year were observed to have gut malrotation during the study period.

SMV=Superior mesenteric vein, SMA=Superior mesenteric artery, DJ=Duodenojejunal junction
and the common clinical features among the patients were abdominal pain and vomiting. In a case series of gut malrotation by Nasir et al., in 2011, nine cases of gut malrotation were documented and two of the cases were aged 3 and 13 years, respectively. These children also presented with abdominal pain and bilious vomiting. Nwankwo and Gboobo in Portharcourt observed in an audit of patients with gut malrotation over a 5-year period that 8 (36.3%) of the 22 patients diagnosed were more than 2 years of age with all presenting with essentially the same symptomatology.

However, in older children, other clinical features such as failure to thrive and malabsorption syndrome have also been documented. Two of our patients had failure to thrive and weight loss in addition to abdominal pain and vomiting. Nakajima et al. in Japan reported a case of malrotation of gut in a 14-year-old boy while Uwaezuoke and Udoye described a 27-year-old man who was initially thought to have appendicitis, but further reevaluation revealed a gut malrotation.

It must be noted that the diagnosis of malrotation in the teenagers may be difficult and a number of patients may be asymptomatic and some may even live their entire lives without any complaint. The absence of specific signs and few signs, especially in the teenage years, usually results in difficulty in making a diagnosis, but most reports have noted that abdominal pain remains a constant feature. However, the site of the abdominal pain in the older children/adults is not specific and so is the nature of the pain which may vary from a persistent aching to a colicky abdominal pain. Pain may be worse with meals and frequency or interval is quite variable. The subjects in this study had mainly intermittent and colicky abdominal pain.

In terms of sex predilection, most authors have observed a male preponderance for the condition. However, in this study, there was an equal sex distribution which is similar to the finding of Ameh and Chirdan in Zaria.

Malrotation of the gut can occur in isolation or it may be associated with other congenital anomalies even in the older child. Such anomalies include the following: absence of kidney and ureter, biliary atresia, congenital diaphragmatic hernia, duodenal or small-bowel stenosis or atresia, duodenal web, gastrochisis, Hirschsprung disease, imperforate anus, intestinal pseudoobstruction, intussusception, meckel diverticulum, omphalocele, pyloric stenosis, and situs inversus. One of the subjects in this study, a 9-year-old female had situs inversus with a right-sided stomach and left-sided liver and gall bladder. Nwankwo and Gboobo on the other hand observed duodenal atresia (44.4%), jejunoileal atresia (22.2%), renal agenesis (5.5%), and intussusception (11%) in their series.

In making a diagnosis of malrotation in any age group, abdominal X-rays may not be very useful; it may be normal or may show distension of the stomach and proximal duodenum by air, with paucity of gas in the distal bowel. Only one of the subjects in our series had this finding. The upper GI series is believed to be a more reliable diagnostic tool for intestinal malrotation and the sensitivity varies from 93% to 100%. However, preoperative diagnosis is best made with an Abd CT scan, but if not available, then an upper GI series with contrast could be diagnostic. Abd CT scan was diagnostic in 3 (60%) of our patients, and this imaging also enabled the diagnosis of situs inversus to be made in one of the subjects.

In terms of complications, midgut volvulus is the most fatal witnessed in this condition and this has also been reported in older children and even in the adults. This was also observed in this study.

Treatment of gut malrotation requires exploratory laparotomy, even if the patient is asymptomatic as there is a constant risk...
of volvulus and vascular compromise, especially with delay in treatment.[1] In our series, the patient with the volvulus did the Abd CT scan 6 months after the request was made due to financial constraints and thus had the complication by the time the exploratory laparotomy was done.

Prognosis of the condition remains excellent with appropriate and early intervention.[1] However, prognosis may also be influenced by other associated anomalies.

CONCLUSIONS

Malrotation of the intestine though commonly seen in infancy is a condition that should be suspected in older children and adults when the patient present with prolonged and recurrent abdominal pain and vomiting. There is a need to have a high index of suspicion for the condition and the use of the Abd CT enhances diagnosis and detection of other associated anomalies.
